## SECTION 1 Altitudinal species ranks

### 1A Nomenclature

Species names follow Flora Europaea<sup>31</sup>.

### 1B Ranking procedure

For each species, its lower and upper distribution margin and its distribution centre were derived from standard floras (Supplementary Table 1; this table provides also abbreviations for mountain regions as used in this Supplementary Information).

These altitudinal profiles were defined using the classical central European concept of vegetation belts (colline, montane, subalpine or treeline, alpine, nival) for the altitudinal distribution of life zones (see ref. 18 in the main text). They were then transformed into 6 altitudinal ranks (Supplementary Table 2) as follows:

Rank 1: species with nival distribution centre;

Rank 2: alpine to nival species that do not descend to the treeline;

Rank 3: alpine centred species which do not descend to the montane belt;

Rank 4: alpine centred species that descend to the montane belt; and species indifferently distributed from the treeline to the alpine; additionally, few treeline/indifferent/nival species from Caucasus, where the upper limit as stated in the literature appeared to be overestimated according to the authors' expert judgement;

Rank 5: species centred in the treeline ecotone or indifferently distributed from the montane to the alpine belts;

Rank 6: species which are montane-centered or indifferently distributed from the montane belt to the treeline.

764 species were classified in this manner before running the analysis. They are listed, together with their altitudinal profiles and ranks, in Appendix I.

### Supplementary Table 1 | Abbreviations for mountain systems and references to standard floras used for the altitudinal species ranking.

Mountain system	Abbreviation in Supplementary Information	Number in Figure 2 and 3 of the main text	Reference to standard flora
Northern Scandes/Sweden	SELAT	1	32
Polar Urals/Russia	RUPUR	2	33,34
Southern Scandes/Norway	NODOV	3	32

### 1C Sensitivity of $D$ to the applied altitudinal classification scheme

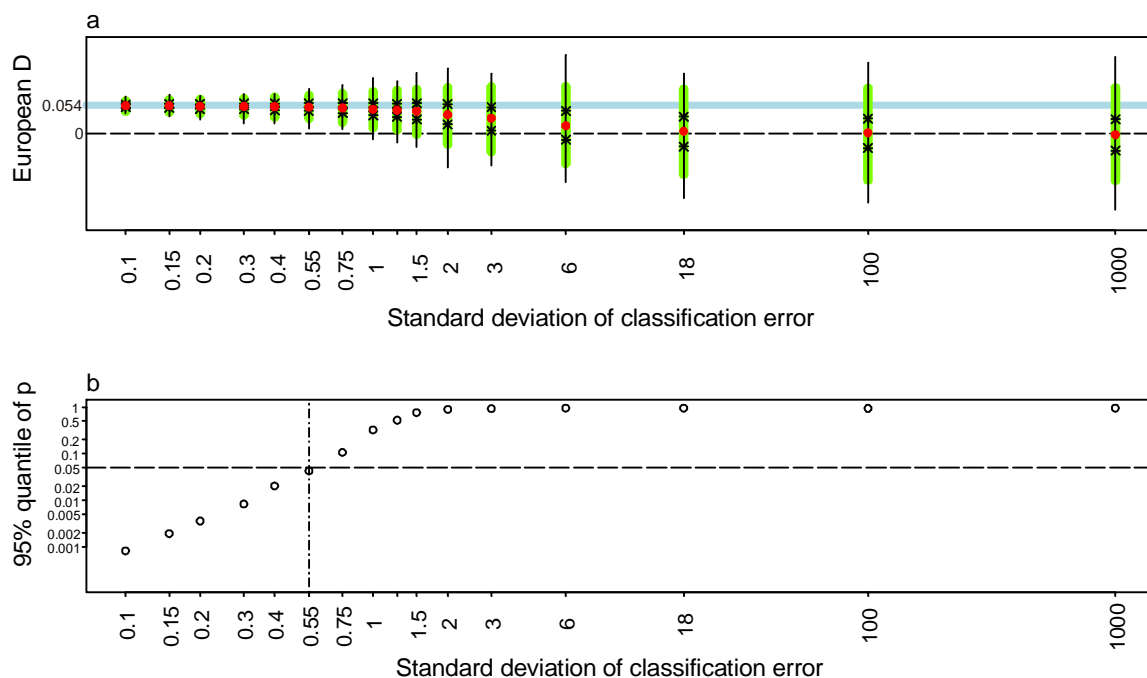

A closer look at the thermic vegetation indicator  $S$  reveals that the influence of any given species on the indicator depends on its altitudinal rank. As shown in Supplementary Table 2, this rank provides us with a range position along the altitudinal gradient at which a given plant species has its ecological optimum. Since an incorrect rank may have been assigned to some of the species, it is of interest to investigate the influence of such an incorrect assignment on  $D$ , i.e., the change in the thermic vegetation indicator  $S$ . As an example, suppose that the thermic vegetation indicator  $S$  of a plot changes from 3.2 to 3.5 between two recording times. Suppose furthermore that this has been mostly caused by a species with altitudinal rank 4 whose cover increased considerably over time. If the rank for this species has been chosen inappropriately and the true rank should be 3, the vegetation indicator should actually have decreased instead of increased between the recording times. If on the other hand the true rank were 5, an even larger increase in  $S$  would have been observed. Thus our results would not be very robust, if the observed changes in scores were supported only by few species on few summits. On the other hand, the more summits and species support the changes, the more stable the results should be.

To further investigate the amount of robustness of our thermic vegetation indicator  $S$  (and its change  $D$ ) with respect to misspecified altitudinal ranks, we consider the following probabilistic model: Consider a (possibly unknown) abundance density that gives the relative abundance of a species at different altitudes. To obtain the altitudinal rank, the researcher tries to identify the altitudinal range where this density attains its mode, i.e. its highest value. By mistake, an incorrect value for the mode may be chosen which in turn may lead to an incorrect altitudinal rank  $r$ . The mode assumed by the

investigator is modeled by assigning a uniformly distributed mode position  $m = r + U$  within the range  $[r - 1/2, r + 1/2]$  implied by the altitudinal rank. To this position  $m$ , we add a normally  $N(0, \sigma^2)$  distributed disturbance  $Z$  representing the distance between the true and the assumed mode of the abundance density. For the resulting disturbed position  $m + Z$ , a disturbed altitudinal rank  $r(m + Z)$  is computed by rounding to the nearest rank. Subsequently the thermic vegetation indicator  $S$  is recomputed based on the disturbed ranks. As the true disturbances are unknown, the computations are repeated many times to get an estimate of the variability induced by using inaccurate altitudinal ranks. The robustness of our results can now be explored by considering several error variances  $\sigma^2$  and checking up to which variance the results remains stable. Our particular interest is in finding out how inaccurate the altitudinal ranks can be, for the changes in  $S$  between the observational periods (i.e.,  $D$ ) to remain statistically significant. Simulations according to the above described probabilistic model gave the following results:

Starting at the original result of 0.054,  $D$  approaches zero with increasing disturbance variance (Supplementary Fig. 1a). Up to an amount of classification errors introduced by disturbances with a standard deviation  $\sigma = 0.55$  ranks, 95% of the  $p$ -values (of 1000 permutation runs per data point in Supplementary Fig. 1b) remain below 0.05. This level of disturbance corresponds to the following average percentages (averaged over 1000 runs) of misclassified species: -3 | 0.13%; -2 | 0.67%; -1 | 20.1%; 0 | 60.6%; 1 | 18.2%; 2 | 0.48%; 3 | 0.13% (notation: distance to original rank | % of misclassified species within the 764 considered species). In other words,  $D$  has a 95% chance to remain significantly positive, even if the correct altitudinal rank has been assigned to only c. 60% of the species.

The focus of this sensitivity analysis has been on the misclassification of species within our proposed classification scheme and the originally applied altitudinal species ranks with the majority of species assigned to the middle ranks. Notice that we did not investigate the influence of considerably different classification schemes on our results, such as a scheme, where the species are distributed equally among the altitudinal ranks.

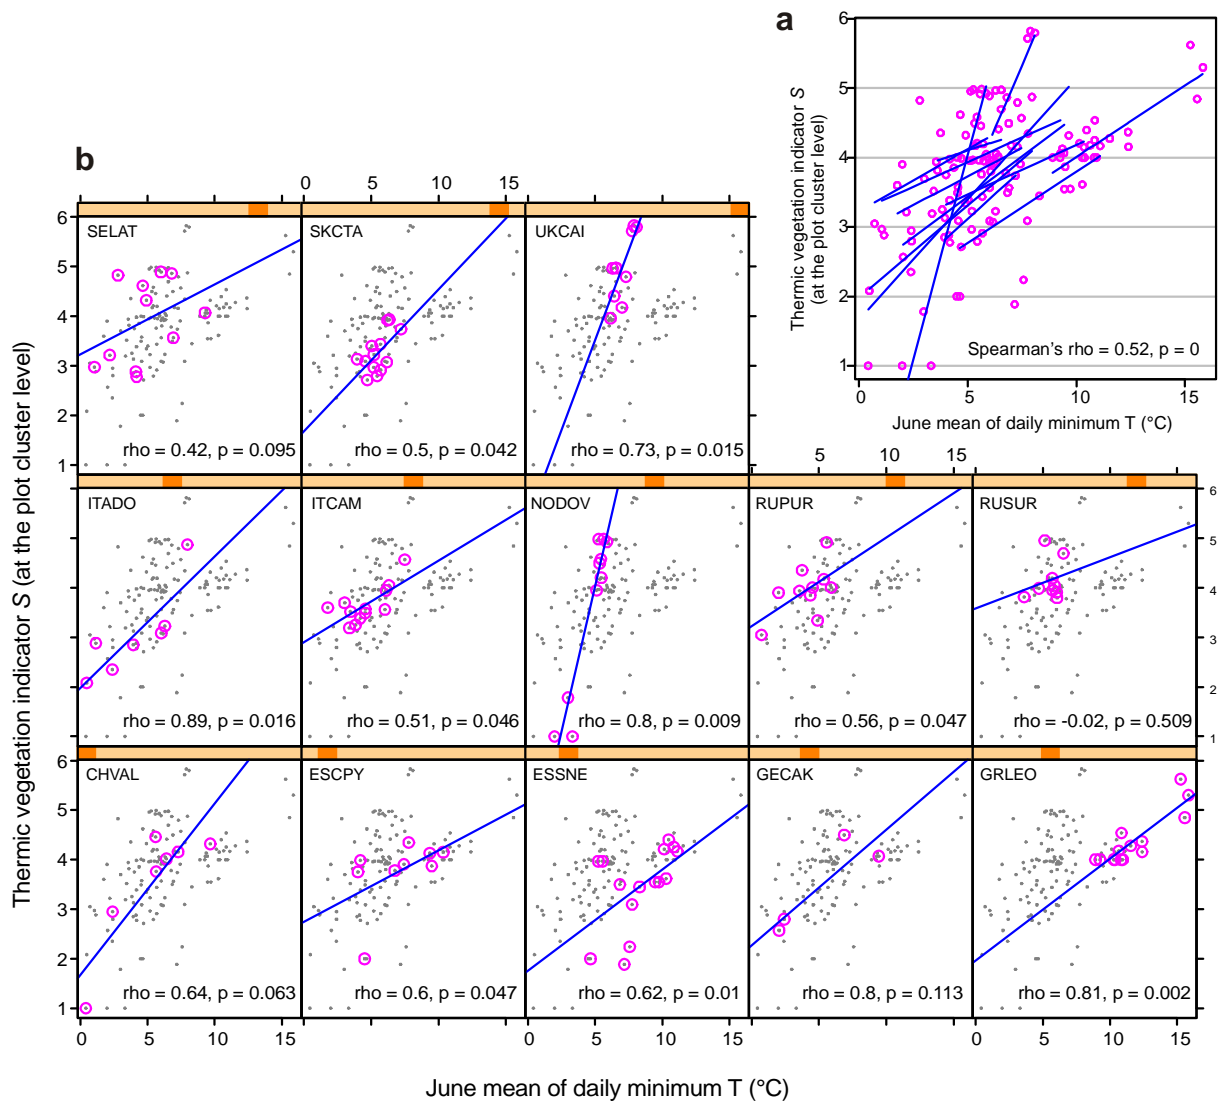

**Supplementary Figure 1 | Sensitivity of the European  $D$  to the applied altitudinal rank classification scheme.** **a**, European  $D$  at increasing simulated rates of misclassification. Points, median, stars, 1<sup>st</sup> and 3<sup>rd</sup> quartile, green bars, 95%-range, black lines, full range of  $D$  simulated in 1000 runs per step on the abscissa. **b**, distribution of  $p$  for  $D$  in the respective 1000 runs. See also the Methods Summary of the main text.

## SECTION 2 Correlation of the thermic vegetation indicator *S* with locally measured temperatures

### 2A Correlation in particular mountain systems

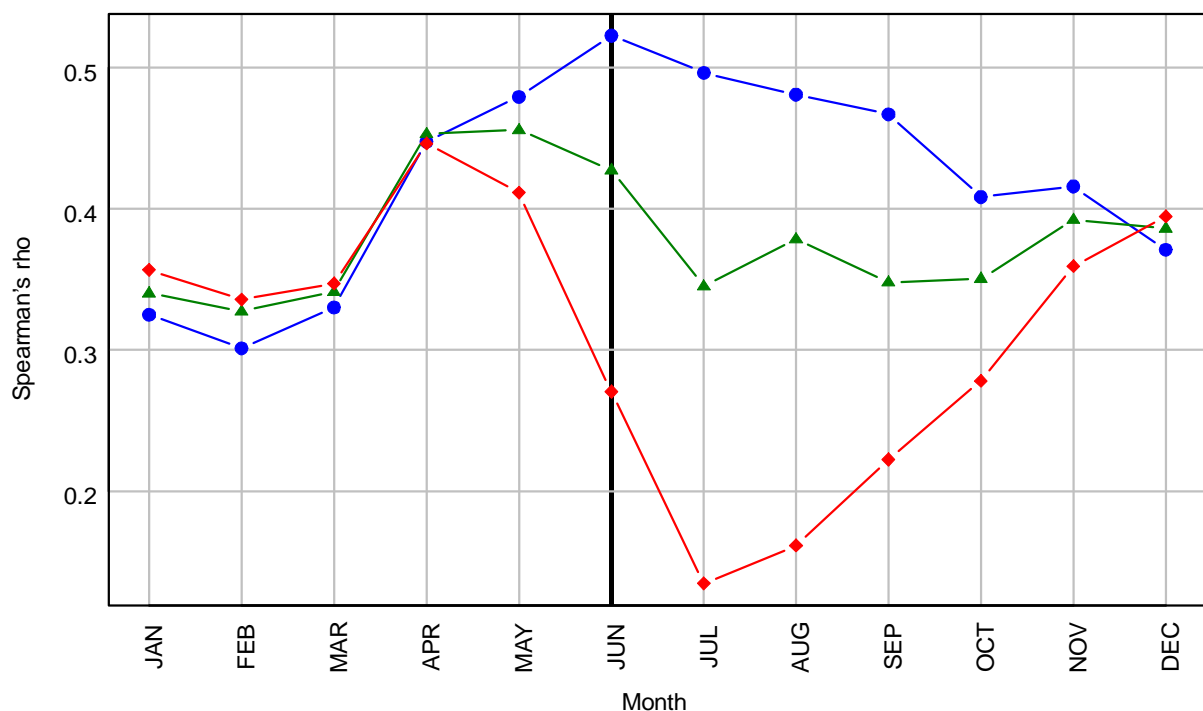

The relationships between the thermic vegetation indicator *S* and the measured soil *T* in the analysed European mountain regions are similar but not the same. *S* is indeed related to temperature in all regions but with different slopes, intercepts and strengths of correlation. There are, however, only two regions (UKCAI, NODOV) with regression slopes which are strongly different from the others (Supplementary Fig. 2). Only temperature loggers which did not fail in any June between 2001 and 2007 are included here ( $n = 131$ ).

**Supplementary Figure 2 | Correlation of the thermic vegetation indicator *S* with habitat temperature in particular mountain regions.** **a**, All mountain regions pooled (redrawn from main text, for comparison to **b**). **b**, Particular mountain regions. Circles, values from the respective region. Grey points, pooled values of all regions. Lines, linear regressions. Spearman's correlation  $\rho$  and the one-sided  $p$  are shown (we test the null hypothesis of no positive correlation). Four of the 17 regions in the dataset are not included here because the number of valid data points was too low due to failure of temperature loggers. For abbreviations of regions' names see Supplementary Tab. 1.

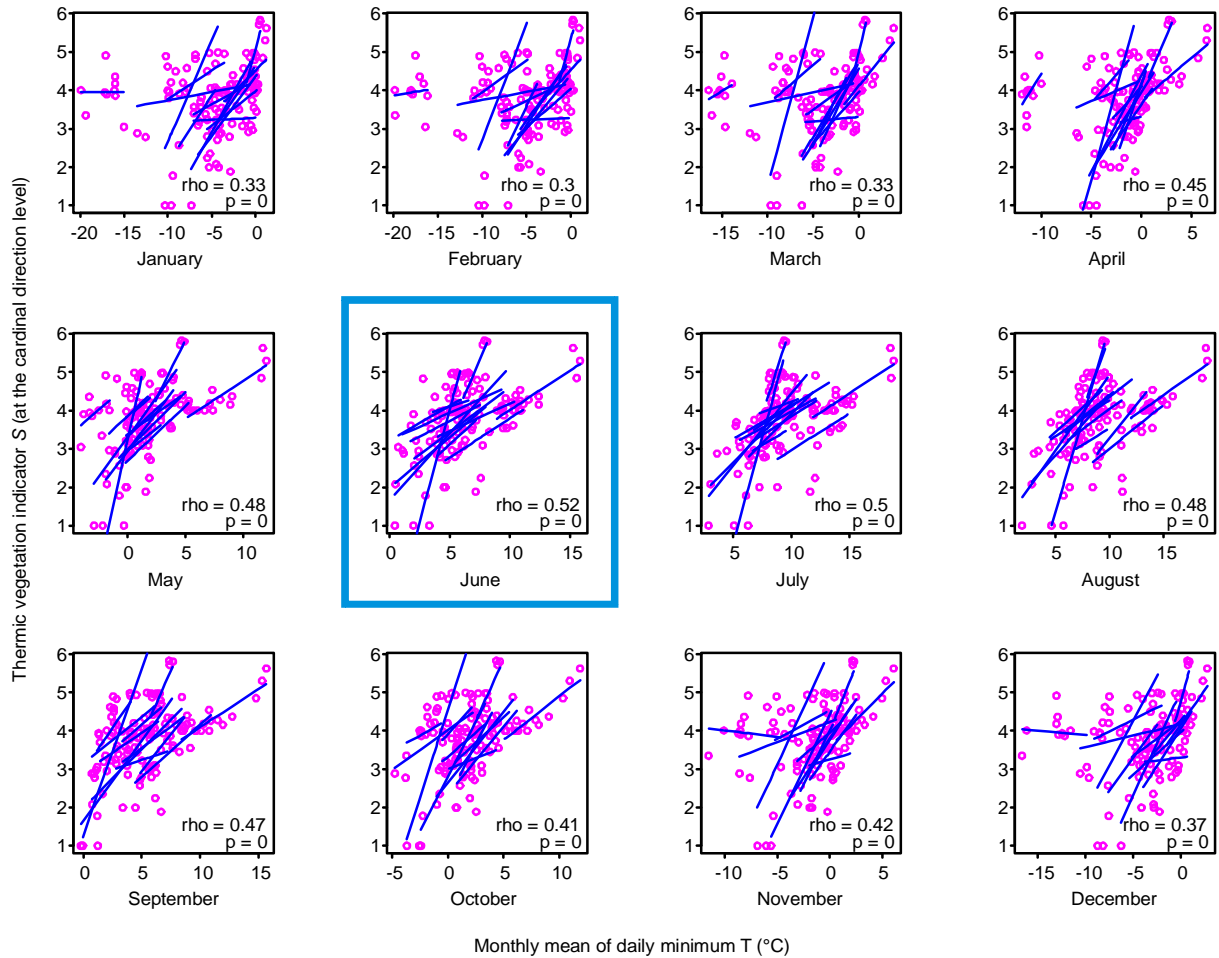

## 2B Why June minimum temperatures?

We tested, using our field vegetation and temperature data, the correlation of  $S_{2008}$  and temperature (T), averaged over 2001-2007, for each month of the year, and for mean of daily minimum ( $T_{\min}$ ), maximum ( $T_{\max}$ ), and mean temperature ( $T_{\text{mean}}$ ) as well. The results are summarized in Supplementary Fig. 3. Using  $T_{\min}$  of June showed the best correlation. We interpret this as follows: i) It is the temperature in the first part of the growing period which is most decisive for plant growth<sup>49</sup>, and see ref. 23 (p.221-226), in the main text. ii) Though temperature was measured in 10cm soil depth, these measurements still include some error due to insolation during daytime, whereas they are buffered against insolation effects at night. Note that the values for  $T_{\min}$ ,  $T_{\text{mean}}$  and  $T_{\max}$  are quite similar from November to May. Under snow protection there is only little diurnal oscillation of T, therefore, daily maxima and minima are not much different.

**Supplementary Figure 3 | Correlation of  $S_{2008}$  with temperature (mean 2001-2007) using different climate predictors.** Temperatures were calculated as mean of each month by using daily minima ( $T_{\min}$ , blue circles), means ( $T_{\text{mean}}$ , green triangles), or maxima ( $T_{\max}$ , red diamonds).

Further, we inspected the patterns of the pooled data (compare Figure 1d in the main text and Supplementary Fig. 2a), using  $T_{\min}$  but calculated for each month of the year (Supplementary Fig. 4). In June the pattern is most consistent as compared to all other months. We are aware that it is certainly not exactly the time span of the calendar month June which is the crucial environmental factor in all the European mountain systems, from the Subarctic to the Mediterranean. Rather it is the temperature regime in the first part of the growing season; this period may differ somewhat from region to region. We derived from the T data measured in field, however, that June was the first month in almost all years where all studied plots were free of snow (data not shown). We conclude from the literature and from the evidence in our data as shown in Supplementary Figs. 3 and 4 that using June minimum temperatures is the best choice for a joint analysis throughout these mountain systems.

**Supplementary Figure 4 | Correlation of  $S$  with  $T_{\min}$  for each month of the year.** Circles, pooled data of plot-clusters from several mountain regions. Blue lines, linear regressions of  $S$  from particular mountain regions on temperature  $T_{\min}$ . Spearman's correlation  $\rho$  and the one-sided  $p$  is drawn (we test the null hypothesis of no positive correlation);  $p < 0.001$  in all months. June  $T_{\min}$  shows the most consistent pattern.

## SECTION 3 Models for $D$

### 3A Final model for $D$

We fit a hierarchical linear mixed effects model for the changes  $D$  in the thermic vegetation indicator  $S$  (see Eq. 1 and 2 in the main text). To set up the model, consider  $n$  mountain regions. Mountain region  $i$  consists of  $n_i$  summits, numbered  $1 \leq j \leq n_i$ . Usually  $n_i = 4$ . Any summit can be split into four cardinal directions  $1 \leq k \leq 4$ , and there are four recording plots  $1 \leq l \leq 4$  for each cardinal direction. Together this leads to  $D_{ijkl}$  for the  $S$  difference of plot  $l$  within cardinal direction  $k$  which is on summit  $j$  within mountain region  $i$ .

Our model is

$$D_{ijkl} = \alpha + \beta_i + \gamma_{ij} + \delta_{ijk} + \varepsilon_{ijkl}. \quad (\text{Supplementary Eq. 1})$$

The most important quantity in our model is the coefficient  $\alpha$  since it measures the overall average change in the plot  $S$ . The other terms are for the random effects and errors: Indeed,  $\beta_i$  indicates the

target region specific random deviation from the overall average  $\alpha$ . Furthermore the coefficients  $\gamma_{ij}$  represent the summit specific fluctuations within the target regions, while  $\delta_{ijk}$  are for the cardinal direction specific fluctuation. Finally  $\varepsilon_{ijkl}$  includes both random fluctuation and measurement error within a local aspect. The variances of the random effects and the error terms  $\varepsilon_{ijkl}$  are of interest, since the variance terms tell us how much fluctuation there is at the respective levels of hierarchy. We used the S-Plus procedure lme to estimate the model and obtained the following estimates:  $\hat{\alpha} = 0.054$ . The standard deviation of the  $\beta_i$  was estimated to be  $\hat{\sigma}_\beta = 0.00092$ . That of the  $\gamma_{ij}$  has been  $\hat{\sigma}_\gamma = 0.0564$ , and that of the  $\delta_{ijk}$  has been  $\hat{\sigma}_\delta = 0.1037$ . The largest component of variance has been the residual standard deviation  $\sigma_\varepsilon = 0.2045$ .

### 3B Other effects on $D$

We now investigate whether the changes in  $S$  (measured by the differences  $D$ ) depend on the altitude of the summit and the latitude of the target region. For this, we added fixed effects for the latitude and the altitude and estimated the following mixed model:

$$D_{ijkl} = \alpha + \beta_i + \gamma_{ij} + \delta_{ijk} + \eta \text{LAT}_i + \nu \text{ALT}_{ij} + \varepsilon_{ijkl}. \quad (\text{Supplementary Eq. 2})$$

Here  $\eta$  is the fixed effect of the latitude  $\text{LAT}_i$  of target region  $i$  and  $\nu$  the fixed effect of the altitude  $\text{ALT}_{ij}$  of summit  $j$  within target region  $i$ . The other notation is as in Suppl. Eq. 1. It turns out that neither the latitude (p-value 0.827) nor the altitude (0.649) contributes significantly to the explanation of  $D$ . The picture remains the same, if the altitude in meters is replaced by dummy variables that indicate whether a summit is highest, second highest (and so on) within its target region. None of the three dummy variables needed to code the relative position of a summit led to a significant p-value (the p-values were 0.149, 0.26, 0.143 respectively.). Further, an ANOVA between the models with and without altitude and latitude led to no significant difference (at alpha = 0.05) in explanatory power. Finally, the model selection criteria AIC and BIC showed better values for the model without the additional variables.

## SECTION 4 Observer errors in visual cover estimates

In this section, we investigate the influence of observer errors on our scores  $S$ . We want to point out that our score  $S$  will remain unchanged, if an observer over- or underestimates cover by the same relative amount for all recorded species. We call such a type of error a *systematic observer error*. Besides systematic observer errors, there are *random observer errors*, fluctuating from measurement to measurement. In Section 4A, we explore further the issue of systematic observer errors. There, we transform the cover estimates from a pilot study such that the estimation errors become close to normally distributed. Within this normal model, we provide a decomposition of the observer errors into a random and a systematic component, and it turns out that random observer errors dominate.

### 4A Systematic and random observer errors

For a more detailed analysis of the relative contributions of random and systematic observer errors to the measurements of species cover, we rely on a pilot study carried out in the two target regions ATHSW and SKCTA. In this investigation, 1x1 m plots have been parallel recorded independently by usually 14 different observers, and with the same recording method as for the study presented in the main text. The goal has been to split the observer errors into two components: a) *random observer error*; this is the error an observer makes, randomly, from one estimate to the next; b) and *systematic observer error*; this is the error component which is systematic, i.e., invariant within an observer but varies between observers, e.g., if a given observer notoriously over-, or under-estimates species cover.

For this purpose, we checked that the variation due to observer errors of the complementary log-log transformed cover  $\log(-\log(\text{cover}))$  can be modelled by a normal distribution. Let

$$Y_{lmo} = \log(-\log(\text{cover}_{lmo})) \quad (\text{Supplementary Eq. 3})$$

denote the transformed cover estimate in plot  $l$  for species  $m$  by observer  $o$ . We set

$$Y_{lmo} = \mu_{lm} + \gamma_o + \varepsilon_{lmo}, \quad (\text{Supplementary Eq. 4})$$

where  $\mu_{lm}$  denotes the true log–log cover for species  $m$  in plot  $l$ ,  $\gamma_o$  denotes the systematic error for observer  $o$ , and  $\varepsilon_{lmo}$  denotes random independent identically distributed observer errors. We used a linear mixed model to estimate the variances of  $\gamma_o$  and  $\varepsilon_{lmo}$  and it turned out that the estimate  $s_o^2$  for  $\text{Var}(\varepsilon_{lmo})$  is much larger (96%) than that of  $\text{Var}(\gamma_o)$  (4%). We thus decided to neglect systematic observer errors in our analyses as presented in the main text.

#### 4B Observer error component in the residual variance at the plot-cluster level

We then focused on the Europe-wide analysis that we present here and used the information obtained from the pilot study to investigate how much of the residual variation at the plot-cluster (i.e., cardinal direction) level can be attributed to observer errors. Our results are therefore based on the assumption that the distribution of observer errors in the pilot study provides a good proxy for the subsequent investigation. In more detail, we simulated random observer errors for the complementary log-log covers of all species occurring within a plot according to a normal  $N(0, s_o^2)$  distribution with  $s_o^2$  being the random observer variance estimated from our pilot study. These errors were added to the actually observed covers and a new plot score  $S_{ijkl}^{*(yr)}$  was computed using the randomly disturbed covers. Here  $(yr)$  denotes the observation year,  $i$  the target region,  $j$  the summit,  $k$  the plot-cluster, and  $l$  the plot within its cluster. The differences

$$u_{ijkl}^{(yr)} := S_{ijkl}^{*(yr)} - S_{ijkl}^{(yr)} \quad (\text{Supplementary Eq. 5})$$

provide the effect of the observer errors on the plot scores. We next remove the residual fluctuation at the plot-cluster level by computing the average plot scores over the four quadrats of each cluster

$$\bar{S}_{ijk}^{(yr)} = \frac{1}{4} \sum_{l=1}^4 S_{ijkl}^{(yr)}. \quad (\text{Supplementary Eq. 6})$$

Simulated plot scores that include only random observer errors but no further residual fluctuation, can then be obtained as

$$S_{ijkl}^{** (yr)} = \bar{S}_{ijk}^{(yr)} + u_{ijkl}^{(yr)}. \quad (\text{Supplementary Eq. 7})$$

We now estimate a mixed model for the change in the plot scores that is based on the simulated differences

$$D_{ijkl}^{**} = S_{ijkl}^{** (yr1)} - S_{ijkl}^{** (yr0)} \quad (\text{Supplementary Eq. 8})$$

and obtain the residual variance  $(s_e^{**})^2$ . We repeat this process over 1000 independent simulation runs and obtain the average residual variance

$$\overline{s_e^{**2}} := \frac{1}{1000} \sum_{j=1}^{1000} (s_e^{**})_j^2. \quad (\text{Supplementary Eq. 9})$$

We then compare  $\overline{s_e^{**2}}$  which is obtained under a model where observer errors are the only source of residual fluctuation with the residual variance  $s_e^2$  from the model based on the actually observed score differences

$$D_{ijkl} = S_{ijkl}^{(yr1)} - S_{ijkl}^{(yr0)}. \quad (\text{Supplementary Eq. 10})$$

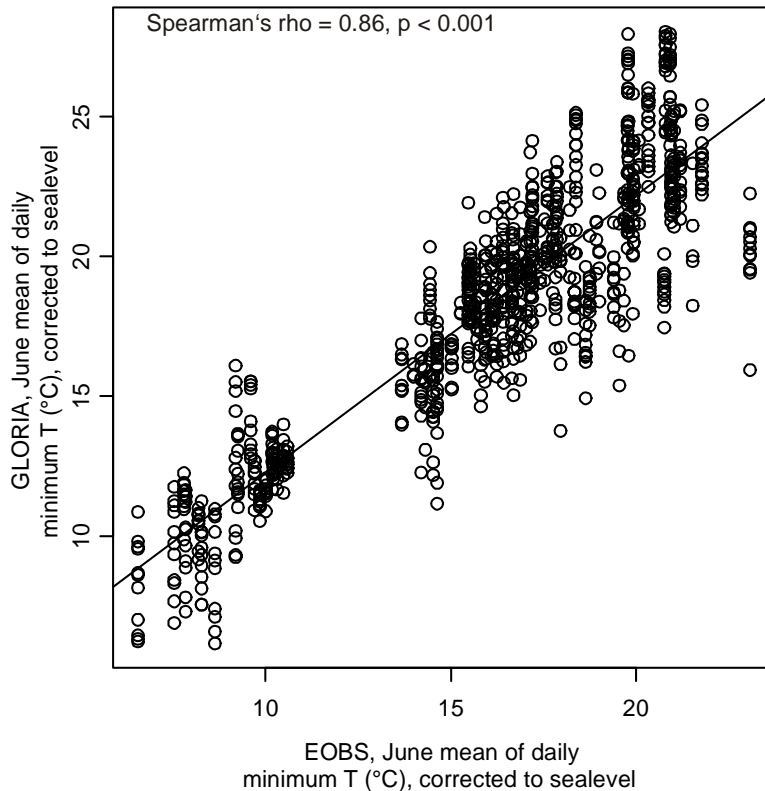

It turns out that the ratio  $\overline{s_e^{**2}}/s_e^2 \approx 0.92$  suggesting that about 92% of the residual fluctuation can be attributed to random observer errors. This does not leave much space for sources of local environmental fluctuation. Notice however that both random observer errors and environmental fluctuation are dealt with appropriately by our linear mixed model. As discussed in Section 4A, the influence of systematic observer errors should be very small.

## SECTION 5 European climate data set (E-OBS data)

E-OBS data were downloaded from <http://eca.knmi.nl/download/ensembles/ensembles.php>. This data set provides, among others, the climate elements  $T_{\min}$ ,  $T_{\text{mean}}$ ,  $T_{\max}$  on a daily basis from 1950 onwards and on a raster of  $0.25 \times 0.25$  geographical degrees. For each mountain region, we defined the grid cell which covered the central point between its recorded summits. In almost all cases, all four summits were located within one cell. Daily information from these cells was used as follows: For each year between 1994 and 2007 we averaged the daily temperature of the three elements for each month. For the Ural Mountains (RUPUR and RUSUR), gaps existed in the E-OBS data in the considered period and, therefore, these two regions were not included in the calculations using E-OBS data (see Figure 3 in the main text).

### 5A Correlation of gridded E-OBS data with GLORIA temperature data measured in the field

First we investigated whether the E-OBS data can represent the local climate development at our recorded summits. For this purpose, we used all available temperature logger data recorded by our GLORIA field measurements for June between 2001 and 2007. If a time series for June of a certain year (due to logger failure) had a gap, this particular series has been excluded. For the remaining instances ( $n = 936$ ), we computed the average daily minimum  $T$  in June, both from the GLORIA time series as well as from the E-OBS data. We calculated and tested the Spearman correlation of the GLORIA data and the respective E-OBS data (Supplementary Fig. 5). As both the GLORIA data (from different summits) and the E-OBS data (from different study regions) were measured at different altitudes, we corrected all temperatures to sealevel beforehand by assuming a lapse rate of  $-5.5 \text{ K / km}$  (ref. 50). This lapse rate is a global rule of thumb and the (unknown) regional lapse rates may deviate. Varying the lapse rate between  $-4.5$  and  $-8.5 \text{ K / km}$  had only marginal effects on the correlation, however. We found a significant correlation between the E-OBS data and our field measurements. This allowed us to adopt prior-2008, prior-2001 -differences in E-OBS temperatures (see Supplementary Section 5B) as surrogate for differences in temperatures at our observed habitats (see Figure 3 in the main text).

**Supplementary Figure 5 | Correlation of gridded European E-OBS data and GLORIA field measurements of temperature  $T_{\min}$ .** Temperatures were measured at different summit altitudes as well as E-OBS cell altitudes but are here corrected to sealevel assuming a lapse rate of  $-5.5\text{K} / \text{km}$ .

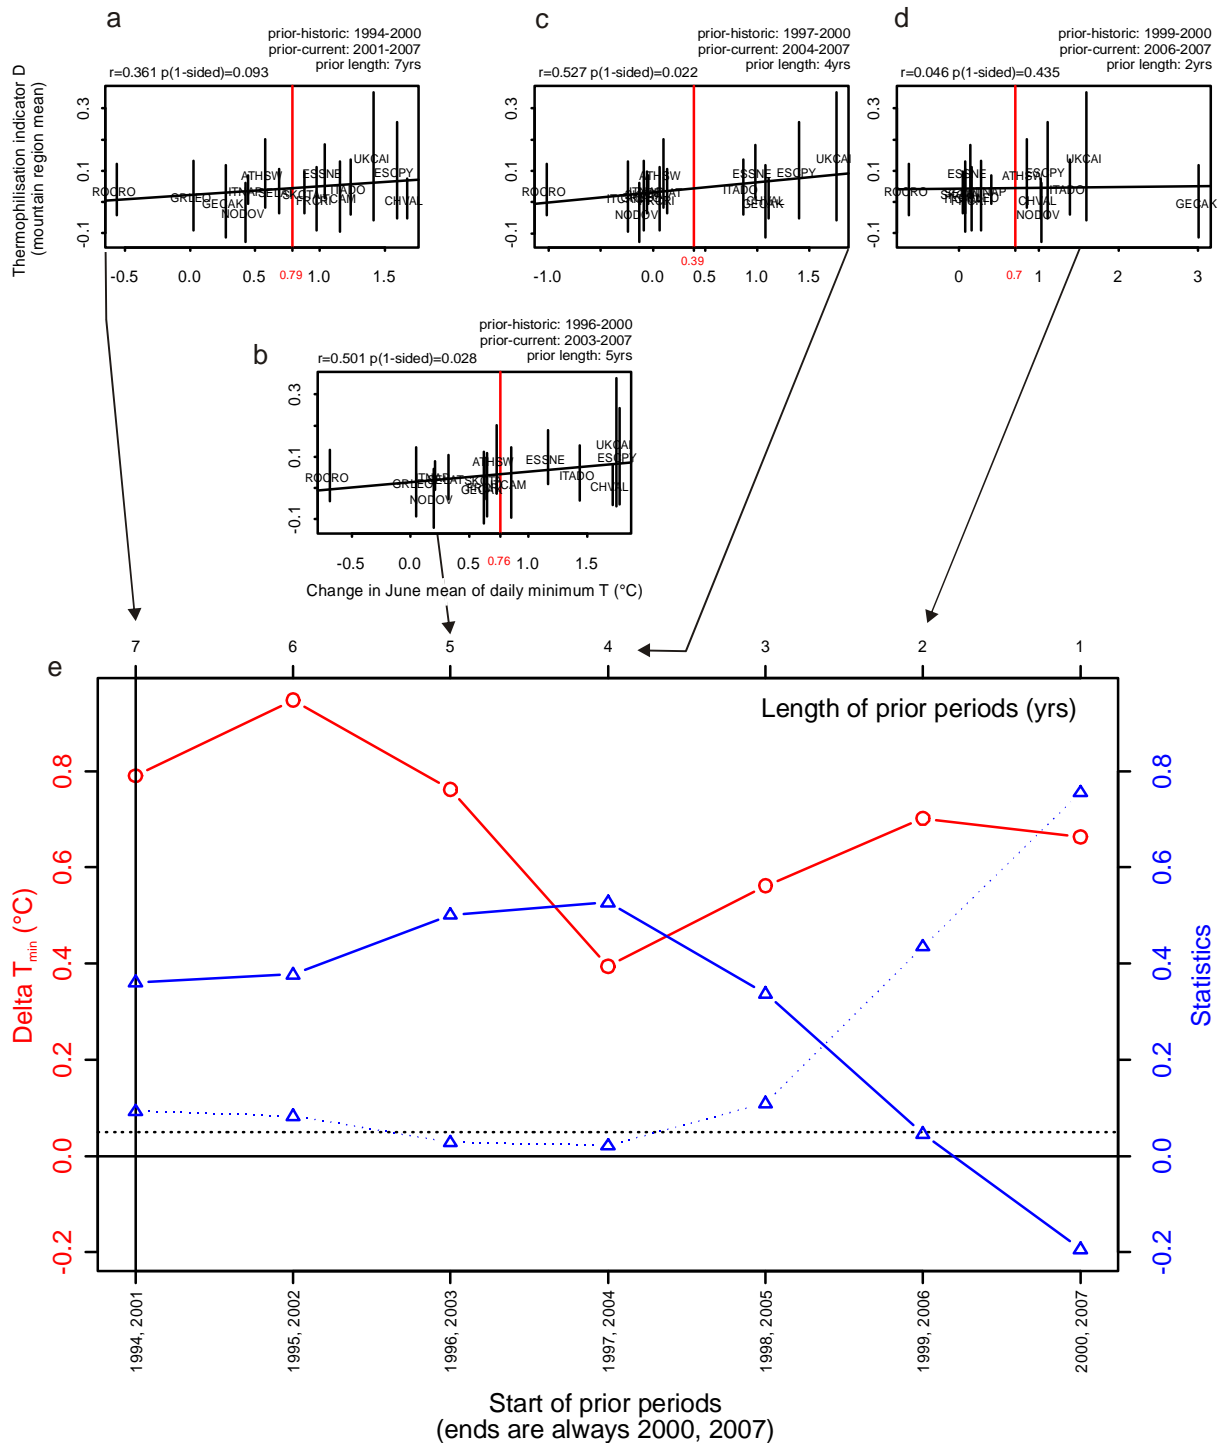

## 5B The prior-period concept

High mountain plants are long-lived. It is therefore unlikely that the climatic conditions short before a recording of plant properties (e.g., their presence and cover) can explain these properties sufficiently. We hypothesize that the climatic conditions of not only one year but of a number of years that preceded the year of plant data sampling influence the plants' status at the sampling time. We term this period as *prior-period* and distinguish a historic (*prior-2001*) from a current (*prior-2008*) period. We hypothesize further that this 'climatic memory' of plants is limited, however. Taking both these effects into account, there should exist a 'best' prior-periods' length representing a trade-off between both effects. Responses of plants to the preceding climatic development should be most visible when using this length of periods.

We tested the correlation between the thermophilisation indicator  $D$  on the level of mountain regions and temperature changes for increasing lengths of the prior-periods. We started with prior-periods of only one year, i.e., we correlated  $D$  with the temperature differences between June 2007 and June 2000 (the years preceding the two recording campaigns). We did not use June 2008 because in a few regions the re-recording started already in June 2008. Then we stepwise increased the length of the prior-periods, i.e., prior-2008 was running from 2006 to 2007 and prior-2001 from 1999 to 2000, and so on. The longest prior-periods were 2001 to 2007 (prior-2008) and 1994 to 2000 (prior-2001). This is a natural limit in our data since the first recording campaign took place in 2001.

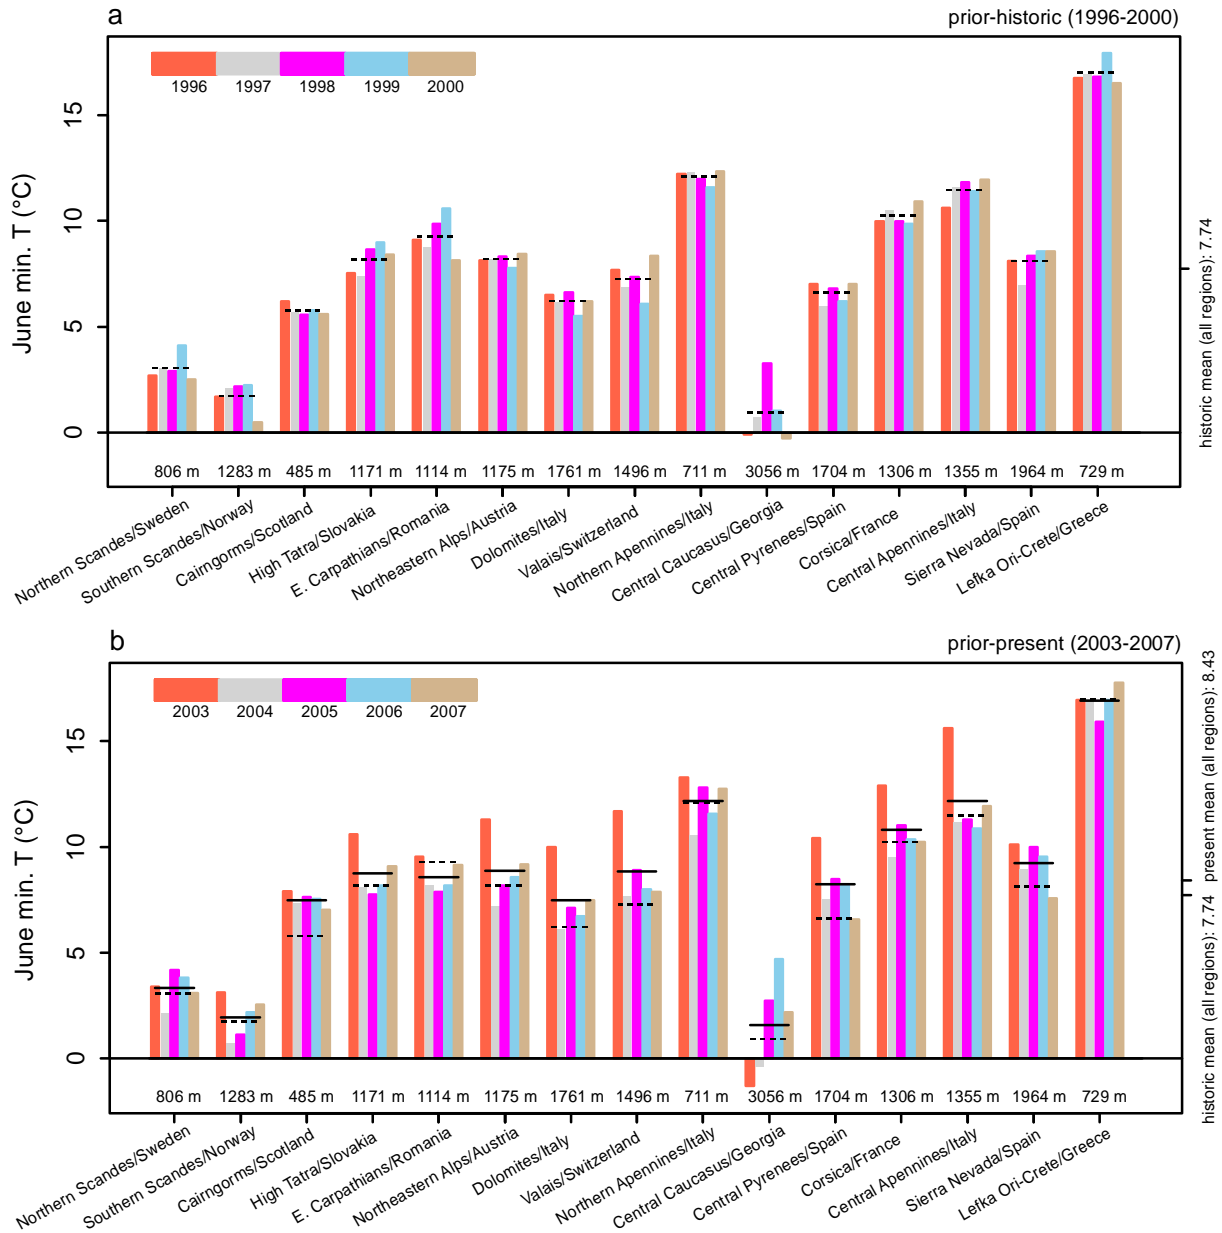

For each pair of prior-periods, we calculated and tested the Pearson's correlation between  $D$  and the temperature difference between prior-2008 and prior-2001 (Supplementary Fig. 6, and compare Figure 3b in the main text). As hypothesised, the amount of correlation peaked somewhere between the shortest and the longest compared prior-periods; it peaked at a prior-period length of four to five years;

moreover, the correlations were significant (at  $\alpha=0.05$ ) at only these two lengths of the prior-periods. We are aware that this is a data-driven best-estimate for a certain climatic period and other results may be obtained if such an analysis is repeated in the coming decades. As the year 2003 brought a remarkable heat wave in most of Europe, we decided to include this year in the prior-periods which were finally selected for the main analysis (see Figure 3 of the main text). The year 2003 (included in the 5-year prior-period) was, however, obviously not extraordinarily influential for  $D$  since the correlation for the 4-year prior-periods was almost equal (formally even slightly better).

**Supplementary Figure 6** (on previous page) | **Comparison of different lengths of prior-periods according the correlation of  $D$  and temperature change.** **a-d**, Four selected prior-periods of different length. Data in **b** are the same as in Figure 3b of the main text. The average delta  $T_{\min}$  between prior-2008 (prior-current) and prior-2001 (prior-historic) is indicated as red line together with its value. Pearson's  $r$  and one-sided  $p$  (we test the null hypothesis of no positive correlation) is indicated. **e**, Comparison of all tested prior-period lengths (on abscissa). Left ordinate and red points, delta  $T_{\min}$  (averaged over all mountain regions) between prior-2008 and prior-2001 (starting years of these periods are indicated on the abscissa). Right ordinate: Blue points connected with solid lines, Pearson's  $r$  of the correlation of  $D$  with delta  $T_{\min}$ ; blue points connected with dotted lines, one-sided  $p$  of the correlation.

Supplementary Fig. 7 (on next page) provides the June  $T_{\min}$  for each mountain region in all years of the prior periods (excluding the Polar Urals and Southern Urals where no E-OBS data are available). It is important to note that the  $T$  values in each region refer to the reference altitude of the respective E-OBS grid cell in which a region is embedded. Therefore, temperatures cannot be directly compared between regions but only their delta  $T$ . It turns out that in the majority of mountain regions (8 of 15) four of the five years in the used prior-2008 period (2003-2007) were warmer than the average  $T$  in the prior-2001 period and that the year 2003 contributes much to this (Supplementary Fig. 7b). If we would, however, consider prior-periods of only four years (compare Supplementary Fig. 6d and e), in an even higher number of regions (9 of 15) three of the four years of the prior-2008 period were warmer than the average over the prior-2001 period in the respective mountain region. This again relativises the role of the 2003-heat wave.

**Supplementary Figure 7 |  $T_{\min}$  in all mountain regions and all years of the prior-periods. a**, The historic, and **b**, the present prior-period. The differing reference altitudes of the relevant E-OBS cells are indicated at the ordinates. Horizontal lines, mountain regions' mean  $T_{\min}$  in the prior-historic (dashed) and the prior-present (solid) period. No data available for Polar Urals and Southern Urals.
